POSIX Lexing with Bitcoded Derivatives

Chengsong Tan

Abstract

Sulzmann and Lu describe a lexing algorithm that calculates Brzozowski derivatives using bitcodes annotated to regular expressions. Their algorithm generates POSIX values which encode the information of how a regular expression matches a string—that is, which part of the string is matched by which part of the regular expression. This information is needed in the context of lexing in order to extract and to classify tokens. The purpose of the bitcodes is to generate POSIX values incrementally while derivatives are calculated. They also help with designing an “aggressive” simplification function that keeps the size of derivatives finitely bounded. Without simplification the size of some derivatives can grow arbitrarily big, resulting in an extremely slow lexing algorithm. In this paper we describe a variant of Sulzmann and Lu’s algorithm: Our variant is a recursive functional program, whereas Sulzmann and Lu’s version involves a fixpoint construction. We (i) prove in Isabelle/HOL that our variant is correct and generates unique POSIX values (no such proof has been given for the original algorithm by Sulzmann and Lu); we also (ii) establish finite bounds for the size of our derivatives.

Keywords and phrases  POSIX matching and lexing, derivatives of regular expressions, Isabelle/HOL

1 Introduction

In the last fifteen or so years, Brzozowski’s derivatives of regular expressions have sparked quite a bit of interest in the functional programming and theorem prover communities. Derivatives of a regular expressions, written \( r \cdot c \), give a simple solution to the problem of matching a string \( s \) with a regular expression \( r \): if the derivative of \( r \) w.r.t. (in succession) all the characters of the string matches the empty string, then \( r \) matches \( s \) (and vice versa). The beauty of Brzozowski’s derivatives [4] is that they are neatly expressible in any functional language, and easily definable and reasoned about in theorem provers—the definitions just consist of inductive datatypes and simple recursive functions. Another attractive feature of derivatives is that they can be easily extended to bounded regular expressions, such as \( r^{\{n\}} \) or \( r^{\{\cdot \cdot n\}} \), where numbers or intervals of numbers specify how many times a regular expression should be used during matching.

However, there are two difficulties with derivative-based matchers: First, Brzozowski’s original matcher only generates a yes/no answer for whether a regular expression matches a string or not. This is too little information in the context of lexing where separate tokens must be identified and also classified (for example as keywords or identifiers). Sulzmann and Lu [15] overcome this difficulty by cleverly extending Brzozowski’s matching algorithm. Their extended version generates additional information on how a regular expression matches a string following the POSIX rules for regular expression matching. They achieve this by adding a second “phase” to Brzozowski’s algorithm involving an injection function. In our own earlier work we provided the formal specification of what POSIX matching means and proved in Isabelle/HOL the correctness of Sulzmann and Lu’s extended algorithm accordingly [2].

The second difficulty is that Brzozowski’s derivatives can grow to arbitrarily big sizes. For example if we start with the regular expression \((a + aa)^*\) and take successive derivatives
according to the character $a$, we end up with a sequence of ever-growing derivatives like

$$(a + aa)^* \xrightarrow{a} (1 + 1a) \cdot (a + aa)^*$$

$$(0 + 0a + 1) \cdot (a + aa)^* + (1 + 1a) \cdot (a + aa)^*$$

$$(0 + 0a + 0) \cdot (a + aa)^* + (1 + 1a) \cdot (a + aa)^* + (0 + 0a + 1) \cdot (a + aa)^* + (1 + 1a) \cdot (a + aa)^*$$

$\ldots$ (regular expressions of sizes 98, 169, 283, 468, 767, \ldots)

where after around 35 steps we run out of memory on a typical computer (we shall define shortly the precise details of our regular expressions and the derivative operation). Clearly, the notation involving 0s and 1s already suggests simplification rules that can be applied to regular regular expressions, for example $0 \cdot r \Rightarrow 0$, $1 \cdot r \Rightarrow r$, $0 + r \Rightarrow r$ and $r + r \Rightarrow r$. While such simple-minded simplifications have been proved in our earlier work to preserve the correctness of Sulzmann and Lu’s algorithm [2], they unfortunately do not help with limiting the growth of the derivatives shown above: the growth is slowed, but some derivatives can still grow rather quickly beyond any finite bound.

Sulzmann and Lu address this “growth problem” in a second algorithm [15] where they introduce bitcoded regular expressions. In this version, POSIX values are represented as bitsequences and such sequences are incrementally generated when derivatives are calculated. The compact representation of bitsequences and regular expressions allows them to define a more “aggressive” simplification method that keeps the size of the derivatives finitely bounded no matter what the length of the string is. They make some informal claims about the correctness and linear behaviour of this version, but do not provide any supporting proof arguments, not even “pencil-and-paper” arguments. They write about their bitcoded incremental parsing method (that is the algorithm to be fixed and formalised in this paper):

“Correctness Claim: We further claim that the incremental parsing method […] in combination with the simplification steps […] yields POSIX parse trees. We have tested this claim extensively […] but yet have to work out all proof details.” [15, Page 14]

**Contributions:** We fill this gap by implementing in Isabelle/HOL our version of the derivative-based lexing algorithm of Sulzmann and Lu [15] where regular expressions are annotated with bitsequences. We define the crucial simplification function as a recursive function, without the need of a fixpoint operation. One objective of the simplification function is to remove duplicates of regular expressions. For this Sulzmann and Lu use in their paper the standard `nub` function from Haskell’s list library, but this function does not achieve the intended objective with bitcoded regular expressions. The reason is that in the bitcoded setting, each copy generally has a different bitcode annotation—so `nub` would never “fire”. Inspired by Scala’s library for lists, we shall instead use a `distinctWith` function that finds duplicates under an “erasing” function that deletes bitcodes before comparing regular expressions. We shall also introduce our own arguments and definitions for establishing the correctness of the bitcoded algorithm when simplifications are included. Finally we establish that the size of derivatives can be finitely bounded.

In this paper, we shall first briefly introduce the basic notions of regular expressions and describe the definition of POSIX lexing from our earlier work [2]. This serves as a reference point for what correctness means in our Isabelle/HOL proofs. We shall then prove the correctness for the bitcoded algorithm without simplification, and after that extend the proof to include simplification. Our Isabelle code including the results from Sec. 5 is available from https://github.com/urbanchr/posix.
2 Background

In our Isabelle/HOL formalisation strings are lists of characters with the empty string being represented by the empty list, written [], and list-cons being written as _ ::_; string concatenation is _ @ _. We often use the usual bracket notation for lists also for strings; for example a string consisting of just a single character c is written [c]. Our regular expressions are defined as the following inductive datatype:

\[ r ::= 0 | 1 | c | r_1 + r_2 | r_1 \cdot r_2 | r^* | r\{n\} \]

where 0 stands for the regular expression that does not match any string, 1 for the regular expression that matches only the empty string and c for matching a character literal. The constructors + and \cdot represent alternatives and sequences, respectively. We sometimes omit the \cdot in a sequence regular expression for brevity. The language of a regular expression, written \( L(r) \), is defined as usual and we omit giving the definition here (see for example [2]).

In our work here we also add to the usual “basic” regular expressions the bounded regular expression \( r\{n\} \) where the \( n \) specifies that \( r \) should match exactly \( n \)-times (it is not included in Sulzmann and Lu’s original work). For brevity we omit the other bounded regular expressions \( r\{-n\} \), \( r\{n\} \) and \( r\{n..m\} \) which specify intervals for how many times \( r \) should match. The results presented in this paper extend straightforwardly to them, too. The importance of the bounded regular expressions is that they are often used in practical applications, such as Snort (a system for detecting network intrusions) and also in XML Schema definitions. According to Björklund et al [3], bounded regular expressions occur frequently in the latter and can have counters of up to ten million. The problem is that tools based on the classic notion of automata need to expand \( r\{n\} \) into \( n \) connected copies of the automaton for \( r \). This leads to very inefficient matching algorithms or algorithms that consume large amounts of memory. A classic example is the regular expression \((a + b)^* \cdot a \cdot (a + b)^{\{n\}} \) where the minimal DFA requires at least \( 2^{n+1} \) states (see [16]). Therefore regular expression matching libraries that rely on the classic notion of DFAs often impose adhoc limits for bounded regular expressions: For example in the regular expression matching library in the Go language and also in Google’s RE2 library the regular expression \( a^{\{100\}} \) is not permitted, because no counter can be above 1000; and in the regular expression library in Rust expressions such as \( a^{\{1000\}}\{100\}\{5\} \) give an error message for being too big. Up until recently,\(^1\) Rust however happily generated automata for regular expressions such as \( a^{\{100\}}\{\{4294967295\} \). This was due to a bug in the algorithm that decides when a regular expression is acceptable or too big according to Rust’s classification (it did not account for the fact that \( a^{\{0\}} \) and similar examples can match the empty string). We shall come back to this example later in the paper.

These problems can of course be solved in matching algorithms where automata go beyond the classic notion and for instance include explicit counters (e.g. [16]). The point here is that Brzozowski derivatives and the algorithms by Sulzmann and Lu can be straightforwardly extended to deal with bounded regular expressions and moreover the resulting code still consists of only simple recursive functions and inductive datatypes. Finally, bounded regular expressions do not destroy our finite boundedness property, which we shall prove later on.

Central to Brzozowski’s regular expression matcher are two functions called nullable and derivative. The latter is written \( r\{c\} \) for the derivative of the regular expression \( r \) w.r.t. the character \( c \). Both functions are defined by recursion over regular expressions.

\(^1\) up until version 1.5.4 of the regex library in Rust; see also CVE-2022-24713.
We can extend this definition to give derivatives w.r.t. strings, namely as \( r \setminus \varepsilon \equiv r \) and \( r \setminus c \equiv (r \setminus c) \cdot s \). Using \textit{nullable} and the derivative operation, we can define a simple regular expression matcher, namely \( \text{match} \ s \ r \equiv \text{nullable}(r \setminus s) \). This is essentially Brzozowski’s algorithm from 1964. Its main virtue is that the algorithm can be easily implemented as a functional program (either in a functional programming language or in a theorem prover). The correctness of \( \text{match} \) amounts to establishing the property:

\[ \text{Proposition 1.} \quad \exists \ s \in L(r) \]  

It is a fun exercise to formally prove this property in a theorem prover. We are aware of a mechanised correctness proof of Brzozowski’s derivative-based matcher in HOL4 by Owens and Slind [12]. Another one in Isabelle/HOL is part of the work by Krauss and Nipkow [8]. And another one in Coq is given by Coquand and Siles [5]. Also Ribeiro and Du Bois give one in Agda [14].

The novel idea of Sulzmann and Lu is to extend this algorithm for lexing, where it is important to find out which part of the string is matched by which part of the regular expression. For this Sulzmann and Lu presented two lexing algorithms in their paper [15]. The first algorithm consists of two phases: first a matching phase (which is Brzozowski’s algorithm) and then a value construction phase. The values encode \textit{how} a regular expression matches a string. Values are defined as the inductive datatype

\[ v ::= \text{Empty} | \text{Char} \ c | \text{Left} v | \text{Right} v | \text{Seq} v_1 v_2 | \text{Stars} vs \]

where we use \( vs \) to stand for a list of values. The string underlying a value can be calculated by a \textit{flat} function, written \( \lfloor \cdot \rfloor \). It traverses a value and collects the characters contained in it (see [2]).

Sulzmann and Lu also define inductively an inhabitation relation that associates values to regular expressions. Our version of this relation is defined by the following six rules:

\begin{align*}
\vdash \text{Empty} : 1 & \quad \vdash v_1 : r_1 & \quad \vdash v_2 : r_2 & \quad \vdash v_1 : r_1 & \quad \vdash v_2 : r_2 \\
\vdash \text{Char} \ c : c & \quad \forall v \in vs_1. \vdash v : r \land |v| \neq \emptyset & \quad \forall v \in vs_1. \vdash v : r \land |v| = \emptyset \quad \text{len} (vs_1 \oplus vs_2) = n \\
\; \vdash \text{Stars} vs : r^* & \quad \vdash \text{Stars} (vs_1 \oplus vs_2) : r^{(n)}
\end{align*}

Note that no values are associated with the regular expression \( \text{Empty} \), since it cannot match any string. Interesting is our version of the rule for \( r^* \) where we require that each value in \( vs \) flattens to a non-empty string. This means if \( r^* \) matches the empty string, the related value must be of the form \( \text{Stars} \ \varepsilon \). But if \( r^* \) “fires” one or more times, then each copy in \( \text{Stars} vs \) needs to match a non-empty string. Similarly, in the rule for \( r^{(n)} \) we require that the
∀ \, v : \text{functions called expressions. Essentially it injects back a character into a value. For this they define two function on values that mirrors (but inverts) the construction of the derivative on regular POSIX values are (the inductive rules are shown in Figure 1).}

\begin{align*}
  ([\ ], \top) & \rightarrow \text{Empty}^{P1} & (s, r_1) & \rightarrow v & (s, r_2) & \rightarrow v & s \notin L \, r_1^{P+L} \\
  ([c], \, c) & \rightarrow \text{Char} \, c & (s, r_1 + r_2) & \rightarrow \text{Left} \, v & (s, r_1 + r_2) & \rightarrow \text{Right} \, v & (s, \emptyset) & \rightarrow \text{Seq} \, v \, v_2
\end{align*}

\begin{align*}
  (s_1, r_1) & \rightarrow v_1 & (s_2, \quad r_2) & \rightarrow v_2 & \text{aka} & s_3 + s_4 & = \top & \land \, s_3 \not\in \emptyset & s_2 \land s_{1} \not\in s_3 & = s_2 \land s_1 \not\in s_3 & = L \, r_1 \land s_4 \in L \, r_2 \\
  (s_1 [s_2, \, r_1 \cdot r_2) & \rightarrow \text{Seq} \, v_1 \, v_2
\end{align*}

\begin{align*}
  ([\ ], \top) & \rightarrow \text{Stars} \, v \, P^\top & (s_1, \top) & \rightarrow v & (s_2, \top) & \rightarrow \text{Stars} \, v \quad | v | \notin \emptyset & \text{aka} & s_3 \not\in \emptyset & \land \, s_3 \not\in \top & s_3 \not\in \emptyset & = s_2 \land s_1 \not\in s_3 & = L \, r \land s_4 \in L \, (\top) \\
  ([\ ], \top^n) & \rightarrow \text{Stars} \, v \, P^n \quad \forall v \in v \, ([\ ], \top) & \rightarrow v & \text{len} \, v = n & \text{aka} & s_3 \not\in \emptyset & = s_2 \land s_1 \not\in s_3 & = L \, r \land s_4 \in L \, (r^n) & \rightarrow \text{Stars} \, v \, v_n^{n+1}
\end{align*}

\textbf{Figure 1} The inductive definition of POSIX values taken from our earlier paper [2]. The ternary relation, written \((s, r) \rightarrow v\), formalises the notion of given a string \(s\) and a regular expression \(r\) what is the unique value \(v\) that satisfies the informal POSIX constraints for regular expression matching.

length of the list \(vs_1 \oplus vs_2\) equals \(n\) (meaning the regular expression \(r\) matches \(n\)-times) and that the first segment of this list contains values that flatten to non-empty strings followed by a segment that only contains values that flatten to the empty string. It is routine to establish how values “inhabiting” a regular expression correspond to the language of a regular expression, namely \(L \, r = \{ | v | \mid \top \, v : r \} \).

In general there is more than one value inhabiting a regular expression (meaning regular expressions can typically match more than one string). But even when fixing a string from the language of the regular expression, there are generally more than one way of how the regular expression can match this string. POSIX lexing is about identifying the unique value for a given regular expression and a string that satisfies the informal POSIX rules (see [13, 9, 11, 15, 17]). Sometimes these informal rules are called maximal munch rule and rule priority. One contribution of our earlier paper is to give a convenient specification for what POSIX values are (the inductive rules are shown in Figure 1).

The clever idea by Sulzmann and Lu [15] in their first algorithm is to define an injection function on values that mirrors (but inverts) the construction of the derivative on regular expressions. Essentially it injects back a character into a value. For this they define two functions called \(\text{mkeps}\) and \(\text{inj}\):

\begin{align*}
  \text{mkeps} & \text{ 1} \quad \text{def} = \text{Empty} \\
  \text{mkeps} (r_1 \cdot r_2) & \quad \text{def} = \text{Seq} \, (\text{mkeps} \, r_1) \, (\text{mkeps} \, r_2) \\
  \text{mkeps} (r_1 + r_2) & \quad \text{def} = \text{if nullable } r_1 \text{ then Left } (\text{mkeps} \, r_1) \text{ else Right } (\text{mkeps} \, r_2) \\
  \text{mkeps} (r^n) & \quad \text{def} = \text{Stars} \, [] \\
  \text{mkeps} (r^{(n)}) & \quad \text{def} = \text{Stars} \, (\text{replicate } n \, (\text{mkeps} \, r))
\end{align*}

\begin{align*}
  \text{inj} & \quad \text{d} \, c \,(\text{Empty}) \quad \text{def} = \text{Char} \, c \\
  \text{inj} (r_1 + r_2) & \, c \,(\text{Left} \, v_1) \quad \text{def} = \text{Left} \,(\text{inj} \, r_1 \, c \, v_1) \\
  \text{inj} (r_1 + r_2) & \, c \,(\text{Right} \, v_2) \quad \text{def} = \text{Right} \,(\text{inj} \, r_2 \, c \, v_2) \\
  \text{inj} (r_1 \cdot r_2) & \, c \,(\text{Seq} \, v_1 \, v_2) \quad \text{def} = \text{Seq} \,(\text{inj} \, r_1 \, c \, v_1 \, v_2) \\
  \text{inj} (r_1 \cdot r_2) & \, c \,(\text{Left} \,(\text{Seq} \, v_1 \, v_2)) \quad \text{def} = \text{Seq} \,(\text{inj} \, r_1 \, c \, v_1 \, v_2) \\
  \text{inj} (r_1 \cdot r_2) & \, c \,(\text{Right} \, v_2) \quad \text{def} = \text{Seq} \,(\text{mkeps} \, r_1) \,(\text{inj} \, r_2 \, c \, v_2) \\
  \text{inj} (r^n) & \, c \,(\text{Seq} \, v \,(\text{Stars} \, v_2)) \quad \text{def} = \text{Stars} \,(\text{inj} \, r \, c \, v \,: \, v_2) \\
  \text{inj} (r^n) & \, c \,(\text{Seq} \, v \,(\text{Stars} \, v_2)) \quad \text{def} = \text{Stars} \,(\text{inj} \, r \, c \, v \,: \, v_2)
\end{align*}
The function \textit{mkeps} is run when the last derivative is nullable, that is the string to be matched is in the language of the regular expression. It generates a value for how the last derivative can match the empty string. In case of \textit{r}(n) we use the function \textit{replicate} in order to generate a list of exactly \textit{n} copies, which is the length of the list we expect in this case. The injection function then calculates the corresponding value for each intermediate derivative until a value for the original regular expression is generated. Graphically the algorithm by Sulzmann and Lu can be illustrated by the following picture where the path from the left to the right involving \textit{derivatives/nullable} is the first phase of the algorithm (calculating successive Brzozowski’s derivatives) and \textit{mkeps/inj}, the path from right to left, the second phase.

The picture shows the steps required when a regular expression, say \textit{r}$_{1}$, matches the string \([a, b, c]\). The first lexing algorithm by Sulzmann and Lu can be defined as:

\[
\begin{align*}
\text{lexer } r [] & \quad \text{def} = \quad \text{if nullable } r \text{ then Some (mkeps } r) \text{ else None} \\
\text{lexer } r (c::s) & \quad \text{def} = \quad \text{case lexer } (r\backslash c)s \text{ of None } \Rightarrow \text{ None } | \text{ Some } v \Rightarrow \text{ Some (inj } r c v)
\end{align*}
\]

We have shown in our earlier paper [2] that this algorithm is correct, that is it generates POSIX values. The central property we established relates the derivative operation to the injection function.

\begin{itemize}
  \item \textbf{Proposition 2.} If \((s, r\backslash c) \rightarrow v\) then \((c::s, r) \rightarrow \text{inj } r c v\).
\end{itemize}

With this in place we were able to prove:

\begin{itemize}
  \item \textbf{Proposition 3.} (1) \(s \not\in L r\) if and only if \(\text{lexer } r \ s = \text{None}.
  \item (2) \(s \in L r\) if and only if \(\exists v. \text{lexer } r \ s = \text{Some } v \land (s, r) \rightarrow v\).
\end{itemize}

In fact we have shown that, in the success case, the generated POSIX value \(v\) is unique and in the failure case that there is no POSIX value \(v\) that satisfies \((s, r) \rightarrow v\). While the algorithm is correct, it is excruciatingly slow in cases where the derivatives grow arbitrarily (recall the example from the Introduction). However it can be used as a convenient reference point for the correctness proof of the second algorithm by Sulzmann and Lu, which we shall describe next.

\section{Bitcoded Regular Expressions and Derivatives}

In the second part of their paper [15], Sulzmann and Lu describe another algorithm that also generates POSIX values but dispenses with the second phase where characters are injected “back” into values. For this they annotate bitcodes to regular expressions, which we define in Isabelle/HOL as the datatype

\[
breg ::= \text{ZERO} | \text{ONE } bs | \text{CHAR } bs c | \text{ALTs } bs rs | \text{SEQ } bs r_{1} r_{2} | \text{STAR } bs r | \text{NT } bs r n
\]
As can be seen, this coding is "lossy" in the sense that it does not record explicitly character values and also not sequence values (for them it just appends two bitsequences). However, bitsequence ▶ Lemma 4. The corresponding value as bitsequence of a corresponding value, then we can always decode the value accurately (see decoding a bit more involved, but the point is that if we have a regular expression \( Stars \) the different alternatives for \( v \). For this Sulzmann and Lu follow Nielsen and Henglein [10] and define a coding function for lists made up of the constants \( Z \) and \( S \). The idea with bitcoded regular expressions is to incrementally generate the value information (for example \( Left \) and \( Right \)) as bitsequences. For this Sulzmann and Lu follow Nielsen and Henglein [10] and define a coding function for how values can be coded into bitsequences.

\[
\begin{align*}
\text{decode'} \, bs \, (1) & \overset{\text{def}}{=} (\text{Empty}, bs) \\
\text{decode'} \, bs \, (c) & \overset{\text{def}}{=} (\text{Char} \, c, bs) \\
\text{decode'} \, (Z::bs) \, (r_1 + r_2) & \overset{\text{def}}{=} \text{let} \, (v, bs_1) = \text{decode'} \, bs \, r_1 \, \text{in} \, (\text{Left} \, v, bs_1) \\
\text{decode'} \, (S::bs) \, (r_1 + r_2) & \overset{\text{def}}{=} \text{let} \, (v, bs_1) = \text{decode'} \, bs \, r_2 \, \text{in} \, (\text{Right} \, v, bs_1) \\
\text{decode'} \, bs \, (r_1 \cdot r_2) & \overset{\text{def}}{=} \text{let} \, (v_1, bs_1) = \text{decode'} \, bs \, r_1 \, \text{in} \\
& \quad \text{let} \, (v_2, bs_2) = \text{decode'} \, bs_1 \, r_2 \, \text{in} \, (\text{Seq} \, v_1 \, v_2, bs_2) \\
\text{decode'} \, (S::bs) \, (r^*) & \overset{\text{def}}{=} (\text{Stars} \, [], bs) \\
\text{decode'} \, (Z::bs) \, (r^*) & \overset{\text{def}}{=} \text{let} \, (v, bs_1) = \text{decode'} \, bs \, r \, \text{in} \\
& \quad \text{let} \, (\text{Stars} \, vs, bs_2) = \text{decode'} \, bs_1 \, (r^*) \, \text{in} \, (\text{Stars} \, v::vs, bs_2) \\
\text{decode'} \, bs \, (r^{(n)}) & \overset{\text{def}}{=} \text{decode'} \, bs \, (r^*) \\
\text{decode} \, bs \, r & \overset{\text{def}}{=} \text{let} \, (v, bs') = \text{decode'} \, bs \, r \, \text{in} \, \text{if} \, bs' = [] \, \text{then Some} \, v \, \text{else None}
\end{align*}
\]

\textbf{Figure 2} Two functions, called \text{decode'} and \text{decode}, for decoding a value from a bitsequence with the help of a regular expression. The first function terminates because in each call the size of the regular expression decreases or stays the same (the size of \( r^{(n)} \) is assumed to be bigger than the size of \( r^* \)). In the star-case where the size stays the same in the second recursive call, the length of the decoded bitsequence is shorter. Therefore a lexicographic measure of the size of the regular expression and the length of the bitsequence decreases in every recursive call.

where \( bs \) stands for bitsequences; \( r \), \( r_1 \) and \( r_2 \) for bitcoded regular expressions; and \( rs \) for lists of bitcoded regular expressions. The binary alternative \( ALT \, bs \, r_1 \, r_2 \) is just an abbreviation for \( ALTs \, bs \, [r_1, r_2] \). The \( NT \)-regular expression, called \( N\text{-Times} \), contains an integer \( n \), which corresponds to how many times \( r^{(n)} \) should fire. For bitsequences we use lists made up of the constants \( Z \) and \( S \). The idea with bitcoded regular expressions is to incrementally generate the value information (for example \( Left \) and \( Right \)) as bitsequences. For this Sulzmann and Lu follow Nielsen and Henglein [10] and define a coding function for how values can be coded into bitsequences.

\[
\begin{align*}
\text{code} \, (\text{Empty}) & \overset{\text{def}}{=} [] \\
\text{code} \, (\text{Char} \, c) & \overset{\text{def}}{=} [] \\
\text{code} \, (\text{Left} \, v) & \overset{\text{def}}{=} Z::\text{code} \, v \\
\text{code} \, (\text{Right} \, v) & \overset{\text{def}}{=} S::\text{code} \, v \\
\text{code} \, (\text{Seq} \, v_1 \, v_2) & \overset{\text{def}}{=} \text{code} \, v_1 @ \text{code} \, v_2 \\
\text{code} \, (\text{Stars} \, []) & \overset{\text{def}}{=} [] \\
\text{code} \, (\text{Stars} \, v::vs) & \overset{\text{def}}{=} Z::\text{code} \, v @ \text{code} \, (\text{Stars} \, vs)
\end{align*}
\]

As can be seen, this coding is "lossy" in the sense that it does not record explicitly character values and also not sequence values (for them it just appends two bitsequences). However, the different alternatives for \( Left \), respectively \( Right \), are recorded as \( Z \) and \( S \) followed by some bitsequence. Similarly, we use \( Z \) to indicate if there is still a value coming in the list of \( Stars \), whereas \( S \) indicates the end of the list. The lossiness makes the process of decoding a bit more involved, but the point is that if we have a regular expression \( \text{and} \) a bitsequence of a corresponding value, then we can always decode the value accurately (see Fig. 2). The function \text{decode} checks whether all of the bitsequence is consumed and returns the corresponding value as \( \text{Some} \, v \); otherwise it fails with \( \text{None} \). We can establish that for a value \( v \) inhabiting a regular expression \( r \), the decoding of its bitsequence never fails (see also [10]).

\textbf{Lemma 4.} If \( \vdash v : r \) then \( \text{decode} \, (\text{code} \, v) \, r = \text{Some} \, v \).

\textbf{Proof.} This follows from the property that \( \text{decode'} \, ((\text{code} \, v) @ bs) \, r = (v, bs) \) holds for any bit-sequence \( bs \) and \( \vdash v : r \). This property can be easily proved by induction on \( \vdash v : r \).
Sulzmann and Lu define the function \textit{internalise} in order to transform (standard) regular expressions into annotated regular expressions. We write this operation as $r^\uparrow$. This internalisation uses the following \textit{fuse} function.

\[
\text{fuse} \left( bs \ (\text{ZERO}) \right) \overset{\text{def}}{=} \text{ZERO} \quad \text{fuse} \left( bs \ (\text{ONE} \ bs') \right) \overset{\text{def}}{=} \text{ONE} \ (bs @ bs') \quad \text{fuse} \left( bs \ (\text{STAR} \ bs') \right) \overset{\text{def}}{=} \text{STAR} \ (bs @ bs') \quad \text{fuse} \left( bs \ (\text{ NT} \ bs') \right) \overset{\text{def}}{=} \text{ NT} \ (bs @ bs')
\]

This function “fuses” a bitsequence to the topmost constructor of a bitcoded regular expressions. A regular expression can then be \textit{internalised} into a bitcoded regular expression as follows:

\[
\begin{align*}
(0)^\uparrow & \overset{\text{def}}{=} \text{ZERO} \\
(1)^\uparrow & \overset{\text{def}}{=} \text{ONE} \\
(c)^\uparrow & \overset{\text{def}}{=} \text{CHAR} \ (bs) \\
(r^\uparrow) & \overset{\text{def}}{=} \text{STAR} \ (bs)
\end{align*}
\]

There is also an \textit{erase}-function, written $r^\downarrow$, which transforms a bitcoded regular expression into a (standard) regular expression by just erasing the annotated bitsequences. We omit the straightforward definition. For defining the algorithm, we also need the functions \textit{bnnullable} and \textit{bmkepss(s)}, which are the “lifted” versions of \textit{nullable} and \textit{mkeps} acting on bitcoded regular expressions.

\[
\begin{align*}
\text{bnnullable} \ (\text{ZERO}) & \overset{\text{def}}{=} \text{False} & \text{bmkepss} \ (\text{ONE} \ bs) & \overset{\text{def}}{=} \text{bs} \\
\text{bnnullable} \ (\text{ONE} \ bs) & \overset{\text{def}}{=} \text{True} & \text{bmkepss} \ (\text{STAR} \ bs) & \overset{\text{def}}{=} \text{bs @ bmkepss} \ (bs) \\
\text{bnnullable} \ (\text{CHAR} \ bs) & \overset{\text{def}}{=} \text{False} & \text{bmkepss} \ (\text{NT} \ bs) & \overset{\text{def}}{=} \text{bs @ bmkepss} \ (bs) \\
\exists r \in rs. \text{bnnullable} \ r & \overset{\text{def}}{=} \text{bnnullable} \ (\text{bs @ bmkepss} \ r) \\
\text{bnnullable} \ (\text{SEQ} \ bs \ r_1 \ r_2) & \overset{\text{def}}{=} \text{bmkepss} \ (\text{STAR} \ bs) \overset{\text{def}}{=} \text{bs @ [S]} \\
\text{bnnullable} \ (\text{ALTS} \ bs) & \overset{\text{def}}{=} \text{False} & \text{else bs @ [Z] @ bmkepss @ bmkepss} \ (\text{NT} \ r \ (n - 1)) \\
\text{bnnullable} \ (\text{NT} \ bs) & \overset{\text{def}}{=} \text{True} & \text{if n = 0 then bs @ [S]} \\
\text{bnnullable} \ (\text{ALTS} \ bs) & \overset{\text{def}}{=} \text{False} & \text{if n = 0 then True else bnnullable} \ r \\
\text{bnnullable} \ (\text{SEQ} \ bs \ r_1 \ r_2) & \overset{\text{def}}{=} \text{bmkepss} \ (\text{r :: rs}) \overset{\text{def}}{=} \text{bnnullable} \ (\text{bs @ bmkepss} \ (r :: rs))
\end{align*}
\]

The key function in the bitcoded algorithm is the derivative of a bitcoded regular expression. This derivative function calculates the derivative but at the same time also the incremental part of the bitsequences that contribute to constructing a POSIX value.

\[
\begin{align*}
(ZERO) \ c & \overset{\text{def}}{=} \text{ZERO} \\
(ONE \ bs) \ c & \overset{\text{def}}{=} \text{ZERO} \\
(CHAR \ bs \ d) \ c & \overset{\text{def}}{=} \text{if} \ c = d \ \text{then ONE} \ bs \ \text{else ZERO} \\
(ALTS \ bs \ rs) \ c & \overset{\text{def}}{=} \text{ALTS} \ bs \ (\text{map} \ (\_ \ c) \ rs) \\
(SEQ \ bs \ r_1 \ r_2) \ c & \overset{\text{def}}{=} \text{if} \ \text{bnnullable} \ r_1 \\
& \quad \text{then ALTS} \ (\text{SEQ} \ (\text{r}_1 \ c) \ r_2) \ (\text{fuse} \ (\text{bmkepss} \ r_1) \ (\text{r}_2 \ c)) \\
& \quad \text{else SEQ} \ (\text{bs} \ (\text{r}_1 \ c) \ r_2) \\
(STAR \ bs) \ c & \overset{\text{def}}{=} \text{SEQ} \ (\text{bs} \ (@ [Z]) \ (\text{r} \ c) \ (\text{STAR} \ r) \\
(NT \ bs) \ c & \overset{\text{def}}{=} \text{if} \ n = 0 \ \text{then ZERO \ else SEQ} \ (\text{bs} \ (@ [Z]) \ (\text{r} \ c) \ (\text{NT} \ r \ (n - 1))
\end{align*}
\]

This function can also be extended to strings, written $r \ \backslash s$, just like the standard derivative. We omit the details. Finally we can define Sulzmann and Lu’s bitcoded lexer, which we call \textit{blexer}:
We also need some auxiliary facts about how the bitcoded operations relate to the “standard”
operations on regular expressions. For example if we build a bitcoded derivative and erase
the result, this is the same as if we first erase the bitcoded regular expression and then
perform the “standard” derivative operation.

Lemma 5. If $\vdash v : r$ then $\text{code} v = \text{retrieve} (r^\dagger) v$.

We also need some auxiliary facts about how the bitcoded operations relate to the “standard”
operations on regular expressions. For example if we build a bitcoded derivative and erase
the result, this is the same as if we first erase the bitcoded regular expression and then
perform the “standard” derivative operation.

Lemma 6. (1) $(r\backslash s)^\dagger = (r^\dagger) \backslash s$
(2) $\text{bnnullable}(r)$ iff $\text{nullable}(r^\dagger)$
(3) $\text{bmkeps}(r) = \text{retrieve} (\text{mkeps}(r^\dagger))$ provided $\text{nullable}(r^\dagger)$

Proof. All properties are by induction on annotated regular expressions.

The only difficulty left for the correctness proof is that the bitcoded algorithm has only
a “forward phase” where POSIX values are generated incrementally. We can achieve the
same effect with $\text{lexer}$ (which has two phases) by stacking up injection functions during the
forward phase. An auxiliary function, called $\text{flex}$, allows us to recast the rules of $\text{lexer}$ in
terms of a single phase and stacked up injection functions.

$$\text{flex} r f :: \text{def} f \quad \text{flex} r f (c::s) :: \text{def} \text{flex}(r\backslash c) (\lambda v. f (\text{inj} r v)) s$$
The point of this function is that when reaching the end of the string, we just need to apply the stacked up injection functions to the value generated by \textit{mkeps}. Using this function we can recast the success case in \textit{lexer} as follows:

\textbf{Lemma 7.} If $\textit{lexer} r s = \text{Some } v$ then $v = \text{flex} \, id_\, s \, (\text{mkeps}(r\setminus s))$.

Note we did not redefine \textit{lexer}, we just established that the value generated by \textit{lexer} can also be obtained by a different method. While this different method is not efficient (we essentially need to traverse the string $s$ twice, once for building the derivative $r\setminus s$ and another time for stacking up injection functions), it helps us with proving that incrementally building up values in \textit{blexer} generates the same result.

This brings us to our main lemma in this section: if we calculate a derivative, say $r\setminus s$, and have a value, say $v$, inhabiting this derivative, then we can produce the result \textit{lexer} generates by applying this value to the stacked-up injection functions that \textit{flex} assembles. The lemma establishes that this is the same value as if we build the annotated derivative $r^\uparrow \setminus s$ and then retrieve the bitcoded version of $v$, followed by a decoding step.

\textbf{Lemma 8 (Main Lemma).} If $\vdash v : r\setminus s$ then $\text{Some } (\text{flex} \, id_\, s \, v) = \text{decode}(\text{retrieve}(r^\uparrow \setminus s) \, v) \, r$

\textbf{Proof.} This can be proved by induction on $s$ and generalising over $v$. The interesting point is that we need to prove this in the reverse direction for $s$. This means instead of cases $[]$ and $c::s$, we have cases $[]$ and $s@[c]$ where we unravel the string from the back.\(^2\)

We can then prove the correctness of \textit{blexer}—it indeed produces the same result as \textit{lexer}.

\textbf{Theorem 9.} $\text{blexer} \, r \, s = \text{lexer} \, r \, s$

This establishes that the bitcoded algorithm \textit{without} simplification produces correct results. This was only conjectured by Sulzmann and Lu in their paper [15]. The next step is to add simplifications.

\section{Simplification}

Derivatives as calculated by Brzozowski’s method are usually more complex regular expressions than the initial one; the result is that derivative-based matching and lexing algorithms are often abysmally slow if the “growth problem” is not addressed. As Sulzmann and Lu wrote, various optimisations are possible, such as the simplifications $0 \, r \Rightarrow 0$, $1 \, r \Rightarrow r$, $0 + r \Rightarrow r$ and $r + r \Rightarrow r$. While these simplifications can considerably speed up the two algorithms in many cases, they do not solve fundamentally the growth problem with derivatives. To see this let us return to the example from the Introduction that shows the derivatives for $(a + aa)^*$. If we delete in the 3rd step all $0$s and $1$s according to the simplification rules shown above we obtain

\[
(a + aa)^* \quad \xrightarrow{[\textit{a,a,a}]} \quad (1 + a) \cdot (a + aa)^* + ((a + aa)^* + (1 + a) \cdot (a + aa)^*)
\]

This is a simpler derivative, but unfortunately we cannot make any further simplifications. This is a problem because the outermost alternatives contains two copies of the same regular expression (underlined with $r$). These copies will spawn new copies in later derivative

\(^2\) Isabelle/HOL provides an induction principle for this way of performing the induction.
steps and they in turn even more copies. This destroys any hope of taming the size of the derivatives. But the second copy of \( r \) in (1) will never contribute to a value, because POSIX lexing will always prefer matching a string with the first copy. So it could be safely removed without affecting the correctness of the algorithm. The issue with the simple-minded simplification rules above is that the rule \( r + r \Rightarrow r \) will never be applicable because as can be seen in this example the regular expressions are not next to each other but separated by another regular expression.

But here is where Sulzmann and Lu’s representation of generalised alternatives in the bitcoded algorithm shines: in \( \text{ALTs} \; bs \; rs \) we can define a more aggressive simplification by recursively simplifying all regular expressions in \( rs \) and then analyse the resulting list and remove any duplicates. Another advantage with the bitsequences in bitcoded regular expressions is that they can be easily modified such that simplification does not interfere with the value constructions. For example we can “flatten”, or de-nest, or spill out, \( \text{ALTs} \) as follows

\[
\text{ALTs} \; bs_1 \; ( (\text{ALTs} \; bs_2 \; rs_2) \; :: \; rs_1 ) \xrightarrow{\text{hsimp}_{bs}} \text{ALTs} \; bs_1 \; ((\text{map } \text{fuse} \; bs_2 \; rs_2) \; @ \; rs_1)
\]

where we just need to fuse the bitsequence that has accumulated in \( bs_2 \) to the alternatives in \( rs_2 \). As we shall show below this will ensure that the correct value corresponding to the original (unsimplified) regular expression can still be extracted.

However there is one problem with the definition for the more aggressive simplification rules described by Sulzmann and Lu. Recasting their definition with our syntax they define the step of removing duplicates as

\[
\text{bsimp} \; (\text{ALTs} \; bs \; rs) \xrightarrow{\text{def}} \text{ALTs} \; bs \; (\text{nub} \; (\text{map} \; \text{bsimp} \; rs))
\]

where they first recursively simplify the regular expressions in \( rs \) (using map) and then use Haskell’s \text{nub}-function to remove potential duplicates in lists. \text{nub} decides if an element is a duplicate by checking whether it is an \textit{exact} copy of an earlier element in the list. While this makes sense when considering the example shown in (1), \text{nub} is the inappropriate function in the case of bitcoded regular expressions. The reason is that in general the elements in \( rs \) will have a different annotated bitsequence and in this way \text{nub} will never find a duplicate to be removed. One correct way to handle this situation is to first \text{erase} the regular expressions when comparing potential duplicates. This is inspired by Scala’s list functions of the form \text{distinctWith} \( rs \; eq \; acc \) where \( eq \) is an user-defined equivalence relation that compares two elements in \( rs \). We define this function in Isabelle/HOL as

\[
\text{distinctWith} \; [] \; eq \; acc \xrightarrow{\text{def}} []
\]

\[
\text{distinctWith} \; (x::xs) \; eq \; acc \xrightarrow{\text{def}} \begin{cases}
\text{if } (\exists \; y \in \; acc. \; eq \; x \; y) \; \text{then} \; \text{distinctWith} \; xs \; eq \; acc \\
\text{else} \; x :: \; \text{distinctWith} \; xs \; eq \; ((\{x\} \cup \; acc)
\end{cases}
\]

where we scan the list from left to right (because we have to remove later copies). In \text{distinctWith}, \( eq \) is intended to be an equivalence relation for bitcoded regular expressions and \( acc \) is an accumulator for bitcoded regular expressions—essentially a set of regular expressions that we have already seen while scanning the list. Therefore we delete an element, say \( x \), from the list provided a \( y \) with \( y \) being equivalent to \( x \) is already in the accumulator; otherwise we keep \( x \) and scan the rest of the list but add \( x \) as another “seen” element to \( acc \). We will use \text{distinctWith} where \( eq \) is an equivalence that deletes bitsequences from bitcoded regular expressions before comparing the components. One way to define this in Isabelle/HOL is by the following recursive function from bitcoded regular expressions to \text{bool}:
26:12 POSIX Lexing with Bitcoded Derivatives

ZERO ≈ ZERO def = True
ONE _ ≈ ONE _ def = True
STAR _ r_1 ≈ STAR _ r_2 def = r_1 ≈ r_2
ALTs _ [] ≈ ALTs _ [] def = True

SEQ _ r_11 r_12 ≈ SEQ _ r_21 r_22 def = r_11 ≈ r_21 ∧ r_12 ≈ r_22

NT _ r_1 n_1 ≈ NT _ r_2 n_2 def = r_1 ≈ r_2 ∧ n_1 = n_2
ALTs _ (r_1 :: rs_1) ≈ ALTs _ (r_2 :: rs_2) def = r_1 ≈ r_2 ∧ ALTs _ rs_1 ≈ ALTs _ rs_2

where all other cases are set to False. This equivalence is clearly a computationally more expensive operation than nub, but is needed in order to make the removal of unnecessary copies to work properly.

Our simplification function depends on three more helper functions, one is called flts and analyses lists of regular expressions coming from alternatives. It is defined by four clauses as follows:

\[
\begin{align*}
\text{flts } [] & \text{ def } = [] \\
\text{flts } (\text{ZERO} :: rs) & \text{ def } = \text{flts } rs \\
\text{flts } (r :: rs) & \text{ def } = r :: \text{flts } rs \\
\end{align*}
\]

The second clause of flts removes all instances of ZERO in alternatives and the third “de-nests” alternatives (but retains the bitsequence bs’ accumulated in the inner alternative). There are some corner cases to be considered when the resulting list inside an alternative is empty or a singleton list. We take care of those cases in the bsimpALTs function; similarly we define a helper function that simplifies sequences according to the usual rules about ZEROs and ONEs:

\[
\begin{align*}
\text{bsimpALTs } bs [] & \text{ def } = \text{ZERO} \\
\text{bsimpALTs } bs [r] & \text{ def } = \text{fuse } bs r \\
\text{bsimpALTs } bs rs & \text{ def } = \text{bsimpALTs } rs \\
\end{align*}
\]

With this in place we can define our simplification function as

\[
\begin{align*}
\text{bsimp } (\text{SEQ } bs r_1 r_2) & \text{ def } = \text{bsimpSEQ } bs (\text{bsimp } r_1) (\text{bsimp } r_2) \\
\text{bsimp } (\text{ALTs } bs rs) & \text{ def } = \text{bsimpALTs } bs (\text{distinctWith } (\text{flts } (\text{map } \text{bsimp } rs)) \approx \varnothing) \\
\text{bsimp } r & \text{ def } = r \\
\end{align*}
\]

We believe our recursive function bsimp simplifies bitcoded regular expressions as intended by Sulzmann and Lu with the small addition of removing “useless” ONEs in sequence regular expressions. There is no point in applying the bsimp function repeatedly (like the simplification in their paper which needs to be applied until a fixpoint is reached) because we can show that bsimp is idempotent, that is

**Proposition 10.** \( \text{bsimp } (\text{bsimp } r) = \text{bsimp } r \)

This can be proved by induction on \( r \) but requires a detailed analysis that the de-nesting of alternatives always results in a flat list of regular expressions. We omit the details since it does not concern the correctness proof.

Next we can include simplification after each derivative step leading to the following notion of bitcoded derivatives:

\[
\begin{align*}
\text{r}_{\text{bsimp}} [] & \text{ def } = r \\
\text{r}_{\text{bsimp}} (c :: s) & \text{ def } = \text{bsimp } (r \setminus c)_{\text{bsimp}} s \\
\end{align*}
\]

and use it in the improved lexing algorithm defined as
blexer \( r s \) \( \text{def} \) let \( r_{\text{der}} = (r^1)_{\text{bsimp}} s \) in if bnullable \( r_{\text{der}} \) then decode (bmkeps \( r_{\text{der}} \)) \( r \) else None

Note that in blexer the derivative \( r_{\text{der}} \) is calculated using the simplifying derivative \( \text{bsimp} \). The remaining task is to show that blexer and blexer\( ^+ \) generate the same answers.

When we first attempted this proof we encountered a problem with the idea in Sulzmann and Lu’s paper where the argument seems to be to appeal again to the retrieve-function defined for the unsimplified version of the algorithm. But this does not work, because desirable properties such as

\[
\text{retrieve } r v = \text{retrieve } (\text{bsimp } r) v
\]
do not hold under simplification—this property essentially purports that we can retrieve the same value from a simplified version of the regular expression. To start with retrieve depends on the fact that the value \( v \) corresponds to the structure of the regular expression \( r \)—but the whole point of simplification is to “destroy” this structure by making the regular expression simpler. To see this consider the regular expression \( r = r' + 0 \) and a corresponding value \( v = \text{Left } v' \). If we annotate bitcodes to \( r \), then we can use retrieve with \( r \) and \( v \) in order to extract a corresponding bitsequence. The reason that this works is that \( r \) is an alternative regular expression and \( v \) a corresponding Left-value. However, if we simplify \( r \), then \( v \) does not correspond to the shape of the regular expression anymore. So unless one can somehow synchronise the change in the simplified regular expressions with the original POSIX value, there is no hope of appealing to retrieve in the correctness argument for blexer\( ^+ \).

For our proof we found it more helpful to introduce the rewriting systems shown in Fig 3. The idea is to generate simplified regular expressions in small steps (unlike the bsimp-function which does the same in a big step), and show that each of the small steps preserves the bitcodes that lead to the POSIX value. The rewrite system is organised such that \( \rightsquigarrow \) is for bitcoded regular expressions and \( \rightsquigarrow^* \) for lists of bitcoded regular expressions. The former essentially implements the simplifications of bsimpSEQ and flts; while the latter implements the simplifications in bsimpALTs. We can show that any bitcoded regular expression reduces in zero or more steps to the simplified regular expression generated by bsimp:

▶ Lemma 11. \( r \rightsquigarrow^* \text{bsimp } r \)

Proof. By induction on \( r \). To establish the property we can use the properties \( rs \rightsquigarrow^* \text{flts } rs \) and \( rs \rightsquigarrow^* \text{distinctWith } rs \approx 0 \).

We can also show that this rewrite system preserves bnullable, that is simplification does not affect nullability:

▶ Lemma 12. If \( r_1 \rightsquigarrow r_2 \) then bnullable \( r_1 \) = bnullable \( r_2 \).

Proof. Straightforward mutual induction on the definition of \( \rightsquigarrow \) and \( \rightsquigarrow^* \). The only interesting case is the rule LD where the property holds since by the side-conditions of that rule the empty string will be in both \( L (rs_a \# [r_1] \# rs_b \# [r_2] \# rs_c) \) and \( L (rs_a \# [r_1] \# rs_b \# rs_c) \).

From this, we can show that bmkeps will produce the same bitsequence as long as one of the bitcoded regular expressions in \( \rightsquigarrow \) is nullable (this lemma establishes the missing fact we were not able to establish using retrieve, as suggested in the paper by Sulzmann and Lu).

▶ Lemma 13. If \( r_1 \rightsquigarrow r_2 \) and bnullable \( r_1 \land \text{bnullable } r_2 \) then bmkeps \( r_1 \) = bmkeps \( r_2 \).
With these lemmas in place we can finally establish that this means that if the algorithm is called with a regular expression

By reverse induction on \( r \). For the unique \( r \) we defined by the POSIX relation \( (s, r) \rightarrow v \), otherwise the algorithm returns \( \text{None} \) when \( s \notin L(r) \) and no such \( v \) exists. This completes the correctness proof for the second POSIX lexing algorithm by Sulzmann and Lu. The interesting point of this algorithm is that the sizes of derivatives do not grow arbitrarily big but can be finitely bounded, which we shall show next.

**Figure 3** The rewrite rules that generate simplified regular expressions in small steps: \( r_1 \rightsquigarrow r_2 \) is for bitcoded regular expressions and \( rs_1 \rightsquigarrow rs_2 \) for lists of bitcoded expressions. Interesting is the \( LD \) rule that allows copies of regular expressions to be removed provided a regular expression earlier in the list can match the same strings.

**Proof.** By straightforward mutual induction on the definition of \( \rightsquigarrow \) and \( \rightsquigarrow^* \). Again the only interesting case is the rule \( LD \) where we need to ensure that \( \text{bmkeps} (rs_1 \@ [r_1] \@ rs_2 \@ r_2) \@ rs_1 = \text{bmkeps} (rs_1 \@ [r_1] \@ rs_2 \@ r_2) \) holds. This is indeed the case because according to the POSIX rules the generated bitsequence is determined by the first alternative that can match the string (in this case being nullable).

Crucial is also the fact that derivative steps and simplification steps can be interleaved, which is shown by the fact that \( \rightsquigarrow \) is preserved under derivatives.

**Lemma 14.** If \( r_1 \rightsquigarrow r_2 \) then \( r_1 \backslash c \rightsquigarrow^* r_2 \backslash c \).

**Proof.** By straightforward mutual induction on the definition of \( \rightsquigarrow \) and \( \rightsquigarrow^* \). The case for \( LD \) holds because \( L ((r_2 \backslash c)^+) \subseteq L ((r_1 \backslash c)^+) \) if and only if \( L (r_2^+) \subseteq L (r_1^+) \).

Using this fact together with Lemma 11 allows us to prove the central lemma that the unsimplified derivative (with a string \( s \)) reduces to the simplified derivative (with the same string).

**Lemma 15.** \( r \backslash s \rightsquigarrow^* r_{bsimp} \backslash s \)

**Proof.** By reverse induction on \( s \) generalising over \( r \).

With these lemmas in place we can finally establish that \( \text{blexer}^+ \) and \( \text{blexer} \) generate the same value, and using Theorem 9 from the previous section that this value is indeed the POSIX value as generated by \( \text{lexer} \).

**Theorem 16.** \( \text{blexer}^+ \ r \ s = \text{blexer} \ r \ s \ ( = \text{lexer} \ r \ s \text{ by Thm. 9}) \)

**Proof.** By unfolding the definitions and using Lemmas 15 and 13.
5 Finite Bound for the Size of Derivatives

In this section let us sketch our argument for why the size of the simplified derivatives with the aggressive simplification function can be finitely bounded. Suppose we have a size function for bitcoded regular expressions, written $\|r\|$, which counts the number of nodes if we regard $r$ as a tree (we omit the precise definition; ditto for lists $\|rs\|$). For this we show that for every $r$ there exists a bound $N$ such that

$$\forall s. \|r \setminus bsimp s\| \leq N$$

Note that the bound $N$ is a bound for all strings, no matter how long they are. We establish this bound by induction on $r$. The base cases for ZERO, ONE bs and CHAR bs c are straightforward. The interesting case is for sequences of the form $SEQ$ bs $r_1$ $r_2$. In this case our induction hypotheses state $\exists N_1. \forall s. \|r_1 \setminus bsimp s\| \leq N_1$ and $\exists N_2. \forall s. \|r_2 \setminus bsimp s\| \leq N_2$. We can reason as follows

$$[(SEQ bs r_1 r_2) \setminus bsimp s] = [bsimp (ALTs bs ((SEQ [] (r_1 \setminus bsimp s) r_2) :: [r_2 \setminus bsimp s'] \mid s' \in Suf(r_1, s)))] \tag{1}$$

$$\leq [distinctWith ((SEQ [] (r_1 \setminus bsimp s) r_2) :: [r_2 \setminus bsimp s'] \mid s' \in Suf(r_1, s))] \approx \mathcal{O} + 1 \tag{2}$$

$$\leq [SEQ [] (r_1 \setminus bsimp s) r_2] + [distinctWith [r_2 \setminus bsimp s'] \mid s' \in Suf(r_1, s)] \approx \mathcal{O} + 1 \tag{3}$$

$$\leq N_1 + [r_2] + 2 + [distinctWith [r_2 \setminus bsimp s'] \mid s' \in Suf(r_1, s)] \approx \mathcal{O} \tag{4}$$

$$\leq N_1 + [r_2] + 2 + l_{N_2} * N_2 \tag{5}$$

where in (1) the set $Suf(r_1, s)$ are all the suffixes of $s$ where $r_1 \setminus bsimp s'$ is nullable ($s'$ being a suffix of $s$). In (3) we know that $\|SEQ [] (r_1 \setminus bsimp s) r_2\|$ is bounded by $N_1 + [r_2] + 1$. In (5) we know the list comprehension contains only regular expressions of size smaller than $N_2$. The list length after $distinctWith$ is bounded by a number, which we call $l_{N_2}$. It stands for the number of distinct regular expressions smaller than $N_2$ (there can only be finitely many of them). We reason similarly for $STAR$ and $NT$.

Clearly we give in this finiteness argument (Step (5)) a very loose bound that is far from the actual bound we can expect. We can do better than this, but this does not improve the finiteness property we are proving. If we are interested in a polynomial bound, one would hope to obtain a similar tight bound as for partial derivatives introduced by Antimirov [1]. After all the idea with $distinctWith$ is to maintain a “set” of alternatives (like the sets in partial derivatives). Unfortunately to obtain the exact same bound would mean we need to introduce simplifications, such as $(r_1 + r_2) \cdot r_3 \rightarrow (r_1 \cdot r_3) + (r_2 \cdot r_3)$, which exist for partial derivatives. However, if we introduce them in our setting we would lose the POSIX property of our calculated values. For example given the regular expressions $(a + ab) \cdot (b + 1)$ and the string $[a, b]$, then our algorithm generates the following correct POSIX value

$$Seq \ (Right \ (Seq \ (Char \ a) \ (Char \ b))) \ (Right \ Empty)$$

Essentially it matches the string with the longer Right-alternative in the first sequence (and then the ‘rest’ with the empty regular expression 1 from the second sequence). If we add the simplification above, then we obtain the following value $Seq \ (Left \ (Char \ a)) \ (Left \ (Char \ b))$ where the Left-alternatives get priority. However, this violates the POSIX rules and we have not been able to reconcile this problem. Therefore we leave better bounds for future work.

Note also that while Antimirov was able to give a bound on the size of his partial derivatives [1], Brzozowski gave a bound on the number of derivatives, provided they are quotient via ACI rules [4]. Brzozowski’s result is crucial when one uses his derivatives for obtaining a DFA (it essentially bounds the number of states). However, this result does not
transfer to our setting where we are interested in the size of the derivatives. For example it is not true that the set of our derivatives \( r \setminus s \) for a given \( r \) and all strings \( s \) is finite (even when simplified). This is because for our annotated regular expressions the bitcode annotation is dependent on the number of iterations that are needed for STAR-regular expressions. This is not a problem for us: Since we intend to do lexing by calculating (as fast as possible) derivatives, the bound on the size of the derivatives is important, not their number.

6 Conclusion

We set out in this work to prove in Isabelle/HOL the correctness of the second POSIX lexing algorithm by Sulzmann and Lu [15]. This follows earlier work where we established the correctness of the first algorithm [2]. In the earlier work we needed to introduce our own specification for POSIX values, because the informal definition given by Sulzmann and Lu did not stand up to formal proof. Also for the second algorithm we needed to introduce our own definitions and proof ideas in order to establish the correctness. Our interest in the second algorithm lies in the fact that by using bitcoded regular expressions and an aggressive simplification method there is a chance that the derivatives can be kept universally small (we established in this paper that for a given \( r \) they can be kept finitely bounded for all strings). Our formalisation is approximately 7500 lines of Isabelle code. A little more than half of this code concerns the finiteness bound obtained in Section 5. This slight “blot” in the latter part is because we had to introduce an intermediate datatype for annotated regular expressions and repeat many definitions for this intermediate datatype. But overall we think this made our formalisation work smoother.

Having proved the correctness of the POSIX lexing algorithm, which lessons have we learned? Well, we feel this is a very good example where formal proofs give further insight into the matter at hand. For example it is very hard to see a problem with \texttt{nub vs distinctWith} with only experimental data—one would still see the correct result but find that simplification does not simplify in well-chosen, but not obscure, examples.

With the results reported here, we can of course only make a claim about the correctness of the algorithm and the sizes of the derivatives, not about the efficiency or runtime of our version of Sulzmann and Lu’s algorithm. But we found the size is an important first indicator about efficiency: clearly if the derivatives can grow to arbitrarily big sizes and the algorithm needs to traverse the derivatives possibly several times, then the algorithm will be slow—excruciatingly slow that is. Other works seem to make stronger claims, but during our formalisation work we have developed a healthy suspicion when for example experimental data is used to back up efficiency claims. For instance Sulzmann and Lu write about their equivalent of \texttt{blexer+ \ldots we can incrementally compute bitcoded parse trees in linear time in the size of the input} [15, Page 14]. Given the growth of the derivatives in some cases even after aggressive simplification, this is a hard to believe claim. A similar claim about a theoretical runtime of \( O(n^2) \) for one specific list of regular expressions is made for the Verbatim lexer, which calculates tokens according to POSIX rules [6]. For this, Verbatim uses Brzozowski’s derivatives like in our work. About their empirical data, the authors write: “The results of our empirical tests [...] confirm that Verbatim has \( O(n^2) \) time complexity.” [6, Section VII]. While their correctness proof for Verbatim is formalised in Coq, the claim about the runtime complexity is only supported by some empirical evidence obtained by using the code extraction facilities of Coq. Given our observation with the “growth problem” of derivatives, this runtime bound is unlikely to hold universally: indeed we tried out their extracted OCaml code with the example \((a + aa)^*\) as a single lexing rule, and it took for
us around 5 minutes to tokenise a string of 40 a’s and that increased to approximately 19 minutes when the string is 50 a’s long. Taking into account that derivatives are not simplified in the Verbatim lexer, such numbers are not surprising. Clearly our result of having finite derivatives might sound rather weak in this context but we think such efficiency claims really require further scrutiny. The contribution of this paper is to make sure derivatives do not grow arbitrarily big (universally). In the example \((a + aa)^*\), all derivatives have a size of 17 or less. The result is that lexing a string of, say, 50 000 a’s with the regular expression \((a + aa)^*\) takes approximately 10 seconds with our Scala implementation of the presented algorithm.\(^3\)

Finally, let us come back to the point about bounded regular expressions. We have in this paper only shown that \(r\{n\}\) can be included, but all our results extend straightforwardly also to the other bounded regular expressions. We find bounded regular expressions fit naturally into the setting of Brzozowski derivatives and the bitcoded regular expressions by Sulzmann and Lu. In contrast bounded regular expressions are often the Achilles’ heel in regular expression matchers that use the traditional automata-based approach to lexing, primarily because they need to expand the counters of bounded regular expressions into \(n\)-connected copies of an automaton. This is not needed in Sulzmann and Lu’s algorithm. To see the difference consider for example the regular expression \(a^{1001} \cdot a^*\), which is not permitted in the Go language because the counter is too big. In contrast we have no problem with matching this regular expression with, say 50 000 a’s, because the counters can be kept compact. In fact, the overall size of the derivatives is never greater than 5 in this example. Even in the example from Section 2, where Rust raises an error message, namely \(a^{1000}\{100\}\{5\}\), the maximum size for our derivatives is a moderate 14.

Let us also return to the example \(a^\{0\}\{1294967295\}\) which until recently Rust deemed acceptable. But this was due to a bug. It turns out that it took Rust more than 11 minutes to generate an automaton for this regular expression and then to determine that a string of just one(!) a does not match this regular expression. Therefore it is probably a wise choice that in newer versions of Rust’s regular expression library such regular expressions are declared as “too big” and raise an error message. While this is clearly a contrived example, the safety guaranties Rust wants to provide necessitate this conservative approach. However, with the derivatives and simplifications we have shown in this paper, the example can be solved with ease: it essentially only involves operations on integers and our Scala implementation takes only a few seconds to find out that this string, or even much larger strings, do not match.

Let us also compare our work to the verified Verbatim++ lexer where the authors of the Verbatim lexer introduced a number of improvements and optimisations, for example memoisation [7]. However, unlike Verbatim, which works with derivatives like in our work, Verbatim++ compiles first a regular expression into a DFA. While this makes lexing fast in many cases, with examples of bounded regular expressions like \(a^{100}\{5\}\) one needs to represent them as sequences of \(a \cdot a \cdot \ldots \cdot a\) (500 a’s in sequence). We have run their extracted code with such a regular expression as a single lexing rule and a string of 50 000 a’s—lexing in this case takes approximately 5 minutes. We are not aware of any better translation using the traditional notion of DFAs so that we can improve on this. Therefore we prefer to stick with calculating derivatives, but attempt to make this calculation (in the future) as fast as possible. What we can guarantee with the presented work is that the maximum size of the derivatives for \(a^{100}\{5\} \cdot a^*\) is never bigger than 9. This means our Scala implementation again only needs a few seconds for this example and matching 50 000 a’s, say.

\(^3\) Our Scala implementation is “hand-crafted” and not generated via Isabelle’s code extraction mechanism.
